

Effect modification: the same predictor behaves differently at different activity levels

114,980 SAE features, full dictionary (BatchTopK k=64, resid_post layer 19) | PROVISIONAL TARGET — #1738 SAE->SAE context arm. The correct target (full-width dense->SAE, task #7) does not exist yet. The two arms rank features at $\rho = 0.933$ at panel width, so SHAPE conclusions survive the swap; LEVELS do not. | CI bands on the 4 most heterogeneous predictors only

FLAT => the single activity-partialled rho is a valid summary. SLOPED or SIGN-FLIPPING => effect modification; the profile replaces the single number. The RIGHTMOST point answers 'among only high-activating features, what explains predictability' — that decile is also the estimable slice (100.0% of its features have $R^2 > 0$), so measurement noise is absent there by construction.
