

How each predictor's concordance decays as controls accumulate
bold = the predictor selected that round (its line ends there — it becomes a control)

Bins per control variable are COARSENEDED as the control set grows (bins = clip(round(400 * (1/k)), 2, 10)) so cells stay populated; later rounds therefore condition LESS finely per variable and residual within-cell confounding grows with round number. The retained-pair fraction is printed on each round's own figure. No confidence intervals — differences under ~0.02 should not be read.
